**Abstract**—In this study, we investigated the impact of unstable and stable interface trap charges ( $Q_{it}$ ) on  $P_S$  switching in metal–ferroelectric–insulator–Si (MFIS) ferroelectric field-effect transistors (FeFETs), which vary with the thickness of the insulator. We also examine how these variations ultimately affect the various performance metrics of MFIS FeFETs. To achieve this, we varied the thickness of the insulator ( $t_{IL}$ ) in MFIS FeFETs to 1.5, 2.0, and 2.5 nm, thereby controlling the amount of  $Q_{it}$  injected from the channel into the ferroelectric (FE)/insulator interface. As  $t_{IL}$  decreases, the amount of  $Q_{it}$  increases, which amplifies the electric field across the FE layer. As a result,  $P_S$  switching enhances, and consequently, the MW characteristics of MFIS FeFETs improve. Furthermore, to analyze this in detail, we employed  $P_S$ – $Q_{it}$  measurements on MFIS FeFETs to simultaneously extract unstable and stable  $Q_{it}$  as well as  $P_S$  and MW. The results show that as  $t_{IL}$  increases to 1.5, 2.0, and 2.5 nm,  $Q_{it}$  during program/erase (PGM/ERS) operations decreases to 100%, 61%, and 54%, respectively. This leads to a corresponding decrease in  $P_S$  to 100%, 59%, and 52%. Additionally, after sufficient delay following the PGM/ERS operations, we observe that the proportion stable  $Q_{it}$  compared to  $P_S$  is 91%, regardless to  $t_{IL}$  and

the remaining 9% of  $P_S$  contributes to the MW property. Consequently, as  $t_{IL}$  increases to 1.5, 2.0, and 2.5 nm, the net charge decreases to 100%, 61%, and 54%, resulting in MW values of 1.85, 1.05, and 0.85 V, respectively. Finally, we analyzed the impact of  $Q_{it}$  generation as a function of  $t_{IL}$  on the variability and endurance characteristics of MFIS FeFETs.

**Index Terms**—Ferroelectric field-effect transistor (FeFET), interface trap charges, memory window, polarization.

## I. INTRODUCTION

HAFNIA-BASED ferroelectric field effect transistors (FeFETs) have recently attracted significant interest as a promising nonvolatile memory (NVM) device for the next generation [1], [2], [3], [4]. This is due to their advantageous features, including compatibility with complementary metal–oxide–semiconductor (CMOS) technology, scalability, and nonvolatility [5], [6], [7]. In particular, FeFETs have become crucial components in neuromorphic computing and in-memory computing applications due to their exceptional reliability, high operational speed, and utilization of multilevel cell (MLC) technology [8], [9], [10]. In addition, FeFETs can be utilized in different configurations, including metal–ferroelectric–insulator–Si (MFIS) structure, metal–ferroelectric–metal–IL–Si (MFMIS) gate stacks with floating metal gate, and metal–IL–ferroelectric–IL–Si (MIFIS) structures that make use of both charge trapping and ferroelectric (FE) switching behavior [11], [12], [13]. The wide range of applications of FeFETs offers limitless possibilities for study.

Given that the MFIS gate-stack is the foundational structure of FeFETs, it is crucial to develop accurate models for different attributes in order to facilitate further study on a wide range of FeFETs [14], [15]. Considerable study has been focused on developing an analytical model of MW because of its critical role in the NVM device [16], [17],

[18]. Yoo et al. [19] presented a new explanation for MW behavior of MFIS FeFET using an analytical model. However, Lim et al. [20] introduced an alternative numerical model of MFIS FeFET, which is described in the following equation:

$$MW = |V_{th,PGM} - V_{th,ERS}| = \left| \frac{2(P_S - Q_{it})}{C_{FE}} \right| \quad (1)$$

where  $P_S$ ,  $Q_{it}$ , and  $C_{FE}$  are the spontaneous polarization, interface trap charges, and capacitance of FE layer, respectively.

On the other hand, Ichihara et al. [21], [22] have stated that  $Q_{it}$  within the MFIS gate-stack can be divided into two distinct components: stable  $Q_{it}$  and unstable  $Q_{it}$ . These components refer to the interaction between the IL and the FE layer [23]. The stable  $Q_{it}$  is the component that is highly correlated with  $P_S$  (about 90% of  $P_S$ , as stated in [21]) and the maintenance of the MW after the detrapping of the unstable  $Q_{it}$  attributed to the minor change of the net charge. However, the unstable  $Q_{it}$  has no significance to  $P_S$  and can be quickly released from its trapped state after the program/erase (PGM/ERS) operation. It is widely accepted that the presence of  $Q_{it}$  degrades the MW of FeFETs. However,  $Q_{it}$  can instead play a positive role in enhancing  $P_S$  switching by increasing the electric field across the FE layer [24], [25], [26], [27], [28], [29], [30], [31]. Specifically, a sufficient amount of  $Q_{it}$  (electrons) injected during the program (PGM) operation can stabilize  $P_S$  switching, leading to an expansion of the MW in MFIS FeFETs. Furthermore, Shin et al. [32], [33] have demonstrated that electrons located at the FE/IL interface during the PGM operation contribute to the improvement of MW in MFIS FeFETs, though they also introduce issues, such as variability, using low-frequency noise spectroscopy.

In this study, we experimentally analyze the relationship between  $Q_{it}$  and  $P_S$  during and after the PGM/ERS operations of MFIS FeFETs. We fabricated MFIS FeFETs with  $t_{IL}$  of 1.5, 2.0, and 2.5 nm, which allowed us to alter the amount of  $Q_{it}$  trapped at the interface between the IL and FE layer during the operation. Subsequently, we conducted a detailed comparison of the  $P_S$  switching and MW characteristics based on the  $Q_{it}$  values for each FeFET. To achieve this, we employed  $P_S$ - $Q_{it}$  measurements that can simultaneously extract stable and unstable  $Q_{it}$ ,  $P_S$ , and MW properties specific time after the PGM/ERS operations of MFIS FeFETs. Based on these findings, we analyzed not only the MW but also the variability and endurance characteristics of MFIS FeFETs in relation to the interaction between  $Q_{it}$  and  $P_S$ . Meanwhile, it should be noted that bulk traps within the IL and FE layers also impact the performance of MFIS FeFETs [32], [33]. However, the  $P_S$ - $Q_{it}$  measurement technique is specialized for directly obtaining and comparing  $Q_{it}$ ,  $P_S$ , and MW. Therefore, this study focuses on the impact of the interaction between  $P_S$  and  $Q_{it}$  on the performance of MFIS FeFETs, rather than bulk traps.

The experimental results show that, when subjected to the same electric field, the FeFET with a 1.5-nm-thick IL has a higher  $Q_{it}$  compared to the FeFETs with 2.0- and 2.5-nm-thick ILs on PGM/ERS, with reductions of 61% and 54%, respectively. As a result, this causes a reduction in  $P_S$  switching to 59% and 52%, respectively. The rise in

the quantity of  $Q_{it}$  generated during PGM/ERS is directly proportional to the decrease in the thickness of the IL. At the same time, the electric field applied to the FE layer spontaneously increases, leading to an improvement in  $P_S$  switching. After a sufficient amount of time has passed since the PGM/ERS procedure, the very easily released and unstable  $Q_{it}$  fades, but the stable  $Q_{it}$  persists, accounting for 91% of the  $P_S$  compensation. Furthermore, the remaining 9% of  $P_S$ , in other words, the net charge, influences the MW of MFIS FeFET. Remarkably, the proportion of the uncompensated  $P_S$  remains consistent regardless of  $t_{IL}$  of the MFIS FeFETs. As a result, MFIS FeFETs with a relatively thin  $t_{IL}$  of 1.5 nm demonstrate easy  $Q_{it}$  injection, yielding a significant net charge and a wide MW of 1.85 V. In contrast, MFIS FeFETs with a thick  $t_{IL}$  of 2.5 nm encounter difficulties in  $Q_{it}$  injection, resulting in a reduced net charge and a narrow MW of 0.85 V.

Typically, in MFIS FeFETs, unstable  $Q_{it}$  detraps immediately after PGM/ERS operations, while stable  $Q_{it}$  compensates for approximately 90% of  $P_S$ , with the remaining 10% of  $P_S$  contributing to the MW [21], [22], [23]. To maintain a high uncompensated 10%  $P_S$  value even after a sufficient delay following PGM/ERS operations, excellent  $P_S$  switching characteristics are essential, enabling the achievement of a wide MW in MFIS FeFETs. Consequently, as  $t_{IL}$  decreases,  $Q_{it}$  injection becomes more active, improving  $P_S$  switching and thereby enhancing the MW characteristics of MFIS FeFETs. However, increased  $Q_{it}$  injection exacerbates variability characteristics. Furthermore, as  $t_{IL}$  increases, the voltage distributed across the insulator during PGM/ERS operations increases, leading to the degradation of endurance characteristics. We emphasize that our experimental findings validate the impact of the interaction between  $Q_{it}$  and  $P_S$  on the performance of MFIS FeFETs. Additionally, our results establish a foundation for future research on FeFETs.

## II. EXPERIMENTAL DETAIL

The detailed fabrication procedures of MFIS FeFET device are described as follows. The 1.5-, 2.0-, and 2.5-nm-thick  $\text{SiO}_2$  is formed on the p-type Si wafer by rapid thermal oxidation (RTO) under 700 °C, 800 °C, and 900 °C, respectively, after diluted HF dipping and SPM cleaning. Then, rapid thermal annealing (RTA) process was performed at 1000 °C under  $\text{N}_2$  atmosphere to enhance the Ch. IL quality. The thickness of each device is carefully measured by spectroscopic ellipsometer. Subsequently, the Zr-doped  $\text{HfO}_2$  ( $\text{Hf}_{0.5}\text{Zr}_{0.5}\text{O}_2$ ) film of 18 nm is formed via plasma-enhanced atomic layer deposition (PEALD) at 320 °C chamber temperature. The precursors used in this step are TEMA-Hf and TEMA-Zr. Lastly, the 50-nm-thick TiN gate metal was formed, and subsequently, the RTA at 600 °C in  $\text{N}_2$  ambient was carried out for the crystallization of FE layer. Keithley-4200A pulse generator and Keysight CX-3324A current analyzer are employed for the electrical analysis.

Fig. 1(a) presents the gate-stack of each device with the key fabrication processes. The MW of each device was assessed under various gate voltage with pulsedwidths of 100  $\mu\text{s}$ , as shown in Fig. 1(b). The maximum MW of each MFIS

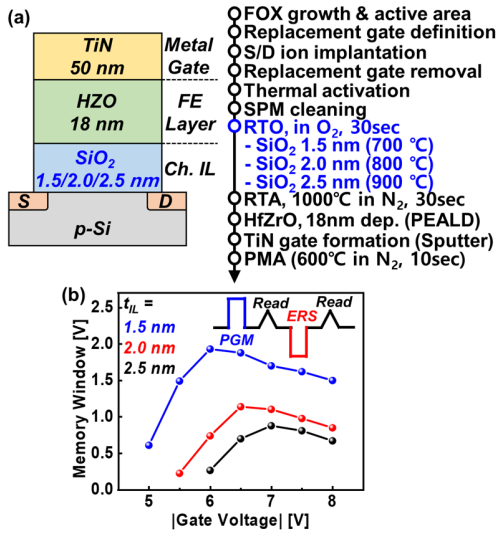

Fig. 1. (a) Schematic of the fabricated device with fabrication process. (b) Measured MW of device with Ch. IL of SiO<sub>2</sub> 1.5, 2, and 2.5 nm for various applied gate voltages.

FeFET device with 1.5-, 2.0-, and 2.5-nm-thick IL was attained at gate voltages of 6.0, 6.5, and 7.0 V, respectively. The further electrical measurements and analyses conducted in this study were conducted under the aforementioned gate voltage conditions.

### III. RESULTS AND DISCUSSION

The pulse scheme of  $P_S-Q_{it}$  measurement is illustrated in Fig. 2, and the detailed process for deriving  $Q_{it}$ ,  $P_S$ , and MW is described elsewhere [21]. Fig. 3(a)–(c) presents the MW,  $\Delta P$ , and  $\Delta Q_{it}$  data of FeFETs with  $t_{IL}$  of 1.5, 2.0, and 2.5 nm, respectively, as a function of delay time. These data were extracted through  $P_S-Q_{it}$  measurements. As  $t_{IL}$  decreases, the amount of  $\Delta Q_{it}$  formed between the FE and the IL during the PGM operation increases, and a significant amount of  $Q_{it}$  can amplify  $E_{FE}$ . This large  $E_{FE}$  contributes to an improvement in  $P_S$  switching behavior. As a result, right after the PGM operation,  $\Delta P$  increases as  $t_{IL}$  decreases. Subsequently, during the delay time, unstable  $Q_{it}$  is detrapped, resulting in a decrease in  $\Delta Q_{it}$ . As a result, the net charge, derived by subtracting  $\Delta Q_{it}$  from  $\Delta P$ , gradually increases, ultimately leading to the emergence of MW. Following a sufficient delay time of 10<sup>3</sup> s, the comparison of MW characteristics among MFIS FeFETs reveals that MW increases as  $t_{IL}$  decreases, as presented in Fig. 3(a)–(c).

In our devices, the saturated MW was observed after 10<sup>3</sup> s, which is known as read-after-write delay (RAWD). However, this study focuses on elucidating the impact of the interaction between  $Q_{it}$  and  $P_S$  on the performances of the FeFETs. Although our research does not propose a direct solution to the RAWD problem, such challenges can be mitigated by adopting a unique operational scheme involving detrapp pulses [22].

Interestingly, as shown in Fig. 4(a), after a sufficient delay time, approximately 90% of  $\Delta P$  is compensated by  $\Delta Q_{it}$  and the remaining  $\Delta P$  contributes to MW. Specifically, unstable  $Q_{it}$ , which does not compensates  $P_S$ , is detrapped, leaving

Fig. 2. Measurement pulse scheme (black) with the gate current (red) responding to the applied biasing voltage for  $P_S-Q_{it}$  separation.

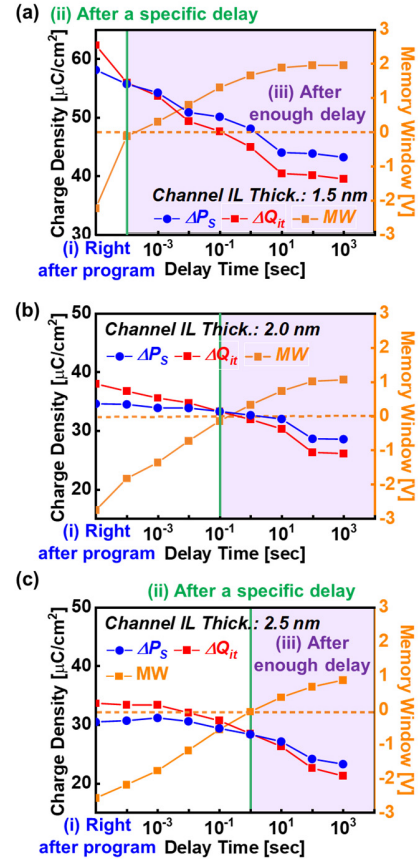

Fig. 3. Calculated  $\Delta P_S$ ,  $\Delta Q_{it}$ , and MW of devices with IL of SiO<sub>2</sub> (a) 1.5, (b) 2.0, and (c) 2.5 nm with respect to the delay time after PGM operation.

stable  $Q_{it}$  coupled with  $P_S$  at the interface. Fig. 4(b) presents the net charge density values along with the corresponding MW properties with respect to  $t_{IL}$  in MFIS FeFETs after 10<sup>3</sup> s following PGM. In our devices, about 9% of  $\Delta P$  is consistently observed as the net charge density, but as  $t_{IL}$  decreases, the value of  $\Delta P$  increases, thereby increasing both the net charge density and MW.

The diagrams in Fig. 5 illustrate the three stages of interaction between  $Q_{it}$  and  $P_S$ , as well as the formation of MW, during the PGM operation of MFIS FeFETs with  $t_{IL}$  values of 1.5 and 2.5 nm, respectively. Fig. 3(a) and (c) provides a description for each stage. Immediately following program operation (i), the generation of  $-Q_{it}$  becomes active within the MFIS gate structure with a 1.5-nm IL. This leads to

Fig. 4. (a) Normalized value of  $\Delta Q_{it}$  compared to  $P_S$  of each devices. (b) Net charge induced on FE/IL interface and the MW characteristics with respect to the IL thickness.

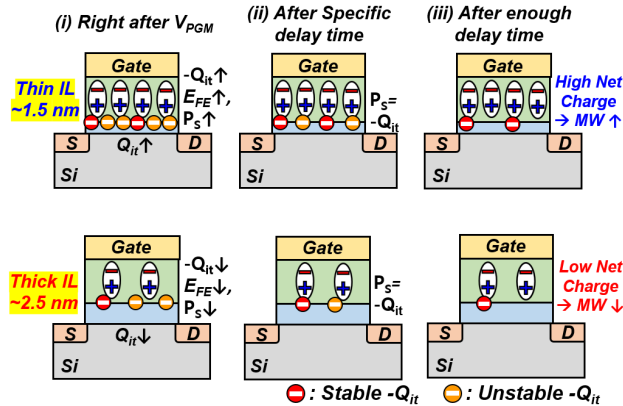

Fig. 5. Schematic of the dynamic alteration of  $P_S$  and  $Q_{it}$  for the MFIS FeFET after the PGM operation for IL thickness of 1.5 and 2.5 nm.

an amplified electric field across the FE layer, hence improving  $P_S$  switching. In contrast, when considering a FeFET with an IL thickness of 2.5 nm, neither the emergence of  $-Q_{it}$  nor the switching of  $P_S$  is active. Following a designated period of time (ii), every MFIS FeFET demonstrates an MW value that is higher than 0. During this stage, the unstable  $-Q_{it}$  gradually becomes annihilated, resulting in a reduction in the overall  $Q_{it}$ . As a result, the net charge density changes from negative to positive when the entire  $Q_{it}$  is subtracted from  $P_S$ . Significantly, as the thickness of the IL increases, the necessary delay time for MW also increases. This indicates that the increase in  $t_{IL}$  not only impedes the injection of  $Q_{it}$  but also hampers its detrapping. Eventually, following a sufficient period of delay (iii), the unstable  $-Q_{it}$  is entirely eliminated, resulting in the presence of just the stable  $-Q_{it}$  combined with  $P_S$ . As  $t_{IL}$  decreases, the high  $P_S$  switching results in a significant net charge density, equivalent to 9% of  $P_S$ , allowing for the attainment of a broad MW range.

As  $t_{IL}$  increases from 1.5 to 2 nm, an abrupt decrease in the MW is observed, as depicted in Fig. 4(b). This is ascribed to a reduction in  $Q_{it}$  during the PGM/ERS operation. It is important to note that the amount of electrons injected from the channel during the PGM operation is significantly higher than the amount of holes injected during the erase (ERS) operation [24], [25], [26], [27], [28], [29], [30], [31]. Fig. 6(a) depicts the measured transfer curve of each device following the PGM/ERS operation. It is worth mentioning that, during PGM operation,  $V_{th}$  consistently changes in relation to the rise in  $t_{IL}$ . However, an apparent decrease in  $V_{th}$  is

Fig. 6. (a) Transfer curve of each device after the PGM and ERS operation. (b) FN tunneling simulation with the modification for direct tunneling of the SiO<sub>2</sub> thickness of 1.5, 2.0, and 2.5 nm.

notably observed for the device with a  $t_{IL}$  of 2 nm during the ERS operation. The decrease in  $V_{th}$  during the ERS operation leads to a significant deterioration in MW. Fig. 6(b) depicts the calculated tunneling current density for SiO<sub>2</sub> IL with thicknesses of 1.5, 2.0, and 2.5 nm. The calculation is based on the Fowler–Nordheim tunneling theory, including the adjustment for direct tunneling [34], [35], [36]. It should be noted that the current density due to tunneling is probably larger, since the effects of trap-assisted tunneling are not taken into account in this specific calculation [37]. The tunneling current density for holes is smaller than that of electrons due to a difference in conduction band and valence band offset [38], [39], [40]. Notably, there is a significant decrease in the density of hole tunneling current when the SiO<sub>2</sub> thickness is 2 nm, whereas the reduction in electron tunneling current density is proportionate across all thicknesses. Since the carrier injected during the ERS operation is a hole, the injected  $Q_{it}$  during the ERS process is greatly reduced. This results in  $P_S$  being uncompensated and causing low  $P_S$  switching behavior in the FE layer. As a result, this leads to a low  $V_{th}$ , which in turn causes the width of the MW to be narrow.

To investigate the impact of the interplay between  $Q_{it}$  and  $P_S$  on the variability of FeFETs, we extracted the  $V_{th}$  variability from 25 individual FeFET devices, as shown in Fig. 7(a)–(c). Interestingly, the  $V_{th}$  variability increased as  $t_{IL}$  decreased, and it was greater in the PGM state compared to the ERS state. This phenomenon is closely related to  $Q_{it}$ . As  $t_{IL}$  decreases,  $Q_{it}$  formation becomes active, leading to an increase in MW. However, variation in  $Q_{it}$  formation within each device can contribute to overall device variability [31], [32]. Additionally, as shown in Fig. 6, the amount of electrons injected from the channel during PGM is greater than the amount of holes injected during ERS, exacerbating the  $V_{th}$  variation. These results demonstrate that while active  $Q_{it}$  formation enhances  $P_S$  switching and MW, there is a tradeoff with device variability.

Fig. 7. Measured pulse  $I$ - $V$  data and variability of MFIS FeFETs (25 devices) with IL thicknesses of (a) 1.5, (b) 2.0, and (c) 2.5 nm.

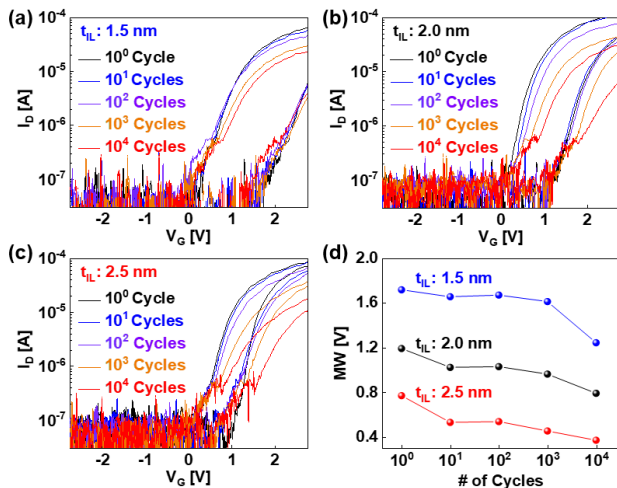

Fig. 8. Measured endurance data of MFIS FeFETs with IL thicknesses of (a) 1.5, (b) 2.0, and (c) 2.5 nm and (d) summarized MW characteristics with respect to the number of cycles.

Finally, we analyzed the impact of the interaction between  $Q_{it}$  and  $P_S$  on the endurance characteristics of FeFETs as shown in Fig. 8(a)–(d). This is because a thicker  $t_{IL}$  results in reduced capacitance of the IL ( $C_{IL}$ ), leading to an increased electric field across the IL during PGM/EERS operations. The greater the wear of the IL during PGM/EERS, the more pronounced the degradation of the subthreshold swing and endurance becomes as the number of cycles increases.

Consequently, in terms of the endurance characteristics, it is desirable to minimize the IL thickness in MFIS FeFETs.

#### IV. CONCLUSION

This study demonstrates how both unstable and stable  $Q_{it}$  affect  $P_S$  in an MFIS gate-stack, impacting the MW, variability, and endurance characteristics. To this end, we adjusted  $t_{IL}$  in MFIS FeFETs to 1.5, 2.0, and 2.5 nm, thereby controlling  $Q_{it}$  injected from the channel. Using the  $P_S$ - $Q_{it}$  measurement technique, we thoroughly analyzed the generation of  $Q_{it}$  and its effects on  $P_S$  as a function of  $t_{IL}$ . According to the results, as  $t_{IL}$  increases,  $Q_{it}$  is not actively generated, leading to a decrease in the MW of MFIS FeFETs and an increase in the detrapp time of trapped  $Q_{it}$ , exacerbating the RAWD issue. Additionally, as  $t_{IL}$  increases, the voltage distributed across the insulator at the gate voltage increases, degrading the endurance characteristics. However, a thinner  $t_{IL}$  increases the amount of  $Q_{it}$ , which enhances the variability of the FeFET device. Finally, we believe that our significant experimental findings establish a foundation for future research on adaptable hafnia FE memory devices.
